FOREWORD

HEALTH TECHNOLOGY ASSESSMENT: A GLOBAL SYSTEM OF NON-MEASUREMENT

The national coordination analysis establishes that measurement failure is structurally endorsed within Spain's HTA system at the upstream level where methodological norms are harmonized and legitimized. However, this finding alone is insufficient to characterize how health technology assessment operates in practice within a highly decentralized system. In Spain, substantive HTA activity, assessment reports, methodological applications, and evaluative judgments occurs predominantly at the regional level. Autonomous communities do not merely implement nationally coordinated guidance; they produce their own assessments, develop analytic practices, and apply HTA outputs directly to decision making. For this reason, the epistemic structure of Spanish HTA cannot be fully understood without examining the regional HTA knowledge base as a distinct object of analysis.

The need for a regional-level interrogation arises from a core methodological principle of the Logit Working Papers: the unit of analysis is the knowledge base that generates and reinforces quantitative claims, not the formal location of authority. In centralized systems, this unit often coincides with a single national HTA agency. In Spain, it does not. Regional HTA bodies possess genuine operational autonomy and generate large volumes of HTA discourse that circulate independently of national coordination mechanisms. These regional outputs constitute an epistemic layer in their own right, with the potential either to modify, resist, or reproduce the numerical assumptions transmitted from above.

Treating regional HTA as analytically subordinate to national coordination would therefore obscure a critical question: does decentralization alter the epistemic content of HTA, or does it simply multiply instances of the same measurement failure? If regions exhibit heterogeneity in analytic practice, that heterogeneity might suggest epistemic instability or partial correction. If, however, regional HTA reproduces the same probability–logit profile observed at the national coordinating level, then decentralization cannot be said to function as a corrective mechanism. Instead, it becomes a mechanism of replication.

This second Logit Working Paper accordingly treats the Spanish regional HTA knowledge base as a distributed epistemic class. It does not aggregate regions numerically, rank autonomous communities, or select exemplar agencies. Rather, it interrogates the collective discourse produced by regional HTA bodies to determine whether the axioms of representational measurement appear anywhere as admissibility conditions for quantitative claims. The question is not whether regions follow national guidance, but whether regional HTA practice possesses measurement theory independently of coordination.

By separating the national coordination layer from the regional HTA knowledge base, the Spanish case becomes analytically decisive. If measurement failure is present only at the coordinating level, regional autonomy might offer epistemic space for correction. If it is reproduced across regions, then measurement failure must be understood as structurally resilient, transmitted through shared

methodological culture rather than imposed by centralized authority. This regional analysis therefore completes the Spanish case by testing whether decentralization modifies the epistemic foundations of HTA—or merely distributes their failure across autonomous institutions.

The objective of this study is to interrogate the regional health technology assessment knowledge base in Spain as a distinct epistemic layer, separate from national coordination mechanisms. The purpose is not to evaluate regional administrative performance, policy outcomes, or the effectiveness of decentralization, but to determine whether the axioms required for scientific measurement are articulated, reinforced, or absent within the collective discourse produced by regional HTA agencies. Using the canonical 24-item diagnostic grounded in representational measurement theory and Rasch measurement principles, the study asks whether regional HTA practice exhibits possession of foundational measurement constraints—unidimensionality, scale-type integrity, invariance, and the logical priority of measurement over arithmetic—or whether regional agencies reproduce the same numerical assumptions already embedded at the national coordinating level.

The findings indicate that Spain's regional HTA knowledge base does not correct or attenuate the measurement failure identified at the national coordination level. Instead, the probability–logit profile shows a structurally similar pattern: weak or absent reinforcement of true measurement axioms combined with strong reinforcement of false measurement propositions associated with utilities, QALYs, aggregation, and simulation modeling. Regional variation does not translate into epistemic diversity. Rather, decentralization functions as a mechanism for reproducing a shared grammar of numerical reasoning across autonomous institutions. Measurement failure in Spanish HTA is therefore not imposed centrally and resisted locally; it is inherited, normalized, and locally instantiated across regions.

The starting point is simple and inescapable: *measurement precedes arithmetic*. This principle is not a methodological preference but a logical necessity. One cannot multiply what one has not measured, cannot sum what has no dimensional homogeneity, cannot compare ratios when no ratio scale exists. When HTA multiplies time by utilities to generate QALYs, it is performing arithmetic with numbers that cannot support the operation. When HTA divides cost by QALYs, it is constructing a ratio from quantities that have no ratio properties. When HTA aggregates QALYs across individuals or conditions, it is combining values that do not share a common scale. These practices are not merely suboptimal; they are mathematically impossible.

The modern articulation of this principle can be traced to Stevens' seminal 1946 paper, which introduced the typology of nominal, ordinal, interval, and ratio scales¹. Stevens made explicit what physicists, engineers, and psychologists already understood: different kinds of numbers permit different kinds of arithmetic. Ordinal scales allow ranking but not addition; interval scales permit addition and subtraction but not multiplication; ratio scales alone support multiplication, division, and the construction of meaningful ratios. Utilities derived from multiattribute preference exercises, such as EQ-5D or HUI, are ordinal preference scores; they do not satisfy the axioms of interval measurement, much less ratio measurement. Yet HTA has, for forty years, treated these utilities as if they were ratio quantities, multiplying them by time to create QALYs and inserting them into models without the slightest recognition that scale properties matter. Stevens' paper

should have blocked the development of QALYs and cost-utility analysis entirely. Instead, it was ignored.

The foundational theory that establishes *when* and *whether* a set of numbers can be interpreted as measurements came with the publication of Krantz, Luce, Suppes, and Tversky's *Foundations of Measurement* (1971) ². Representational Measurement Theory (RMT) formalized the axioms under which empirical attributes can be mapped to numbers in a way that preserves structure. Measurement, in this framework, is not an act of assigning numbers for convenience, it is the discovery of a lawful relationship between empirical relations and numerical relations. The axioms of additive conjoint measurement, homogeneity, order, and invariance specify exactly when interval scales exist. RMT demonstrated once and for all that measurement is not optional and not a matter of taste: either the axioms hold and measurement is possible, or the axioms fail and measurement is impossible. Every major construct in HTA, utilities, QALYs, DALYs, ICERs, incremental ratios, preference weights, health-state indices, fails these axioms. They lack unidimensionality; they violate independence; they depend on aggregation of heterogeneous attributes; they collapse under the requirements of additive conjoint measurement. Yet HTA proceeded, decade after decade, without any engagement with these axioms, as if the field had collectively decided that measurement theory applied everywhere except in the evaluation of therapies.

Whereas representational measurement theory articulates the axioms for interval measurement, Georg Rasch's 1960 model provides the only scientific method for transforming ordered categorical responses into interval measures for latent traits ³. Rasch models uniquely satisfy the principles of specific objectivity, sufficiency, unidimensionality, and invariance. For any construct such as pain, fatigue, depression, mobility, or need, Rasch analysis is the only legitimate means of producing an interval scale from ordinal item responses. Rasch measurement is not an alternative to RMT; it is its operational instantiation. The equivalence of Rasch's axioms and the axioms of representational measurement was demonstrated by Wright, Andrich and others as early as the 1970s. In the latent-trait domain, the very domain where HTA claims to operate; Rasch is the only game in town ⁴.

Yet Rasch is effectively absent from all HTA guidelines, including NICE, PBAC, CADTH, ICER, SMC, and PHARMAC. The analysis demands utilities but never requires that those utilities be measured. They rely on multiattribute ordinal classifications but never understand that those constructs be calibrated on interval or ratio scales. They mandate cost-utility analysis but never justify the arithmetic. They demand modelled QALYs but never interrogate their dimensional properties. These guidelines do not misunderstand Rasch; they do not know it exists. The axioms that define measurement and the model that makes latent trait measurement possible are invisible to the authors of global HTA rules. The field has evolved without the science that measurement demands.

How did HTA miss the bus so thoroughly? The answer lies in its historical origins. In the late 1970s and early 1980s, HTA emerged not from measurement science but from welfare economics, decision theory, and administrative pressure to control drug budgets. Its core concern was *valuing health states*, not *measuring health*. This move, quiet, subtle, but devastating, shifted the field away from the scientific question "What is the empirical structure of the construct we intend to

measure?” and toward the administrative question “How do we elicit a preference weight that we can multiply by time?” The preference-elicitation projects of that era (SG, TTO, VAS) were rationalized as measurement techniques, but they never satisfied measurement axioms. Ordinal preferences were dressed up as quasi-cardinal indices; valuation tasks were misinterpreted as psychometrics; analyst convenience replaced measurement theory. The HTA community built an entire belief system around the illusion that valuing health is equivalent to measuring health. It is not.

The endurance of this belief system, forty years strong and globally uniform, is not evidence of validity but evidence of institutionalized error. HTA has operated under conditions of what can only be described as *structural epistemic closure*: a system that has never questioned its constructs because it never learned the language required to ask the questions. Representational measurement theory is not taught in graduate HTA programs; Rasch modelling is not part of guideline development; dimensional analysis is not part of methodological review. The field has been insulated from correction because its conceptual foundations were never laid. What remains is a ritualized practice: utilities in, QALYs out, ICERs calculated, thresholds applied. The arithmetic continues because everyone assumes someone else validated the numbers.

This Logit Working Paper series exposes, through probabilistic and logit-based interrogations of AI large language national knowledge bases, the scale of this failure. The results display a global pattern: true statements reflecting the axioms of measurement receive weak endorsement; false statements reflecting the HTA belief system receive moderate or strong reinforcement. This is not disagreement. It is non-possession. It shows that HTA, worldwide, has developed as a quantitative discipline without quantitative foundations; a confused exercise in numerical storytelling.

The conclusion is unavoidable: HTA does not need incremental reform; it needs a scientific revolution. Measurement must precede arithmetic. Representational axioms must precede valuation rituals. Rasch measurement must replace ordinal summation and utility algorithms. Value claims must be falsifiable, protocol-driven, and measurable; rather than simulated, aggregated, and numerically embellished.

The global system of non-measurement is now visible. The task ahead is to replace it with science.

DISCLAIMER

This analysis is generated through the structured interrogation of a large language model (LLM) applied to a defined documentary corpus and is intended solely to characterize patterns within an aggregated knowledge environment. It does identify, assess, or attribute beliefs, intentions, competencies, or actions to any named individual, faculty member, student, administrator, institution, or organization. The results do not constitute factual findings about specific persons or programs, nor should they be interpreted as claims regarding professional conduct, educational quality, or compliance with regulatory or accreditation standards. All probabilities and logit values reflect model-based inferences about the presence or absence of concepts within a bounded textual ecosystem, not judgments about real-world actors. The analysis is exploratory, interpretive, and methodological in nature, offered for scholarly discussion of epistemic structures rather than evaluative or legal purposes. Any resemblance to particular institutions or practices is contextual and non-attributive, and no adverse implication should be inferred.

. INTERROGATING THE LARGE LANGUAGE MODEL

A large language model (LLM) is an artificial intelligence system designed to understand, generate, and manipulate human language by learning patterns from vast amounts of text data. Built on deep neural network architectures, most commonly transformers, LLMs analyze relationships between words, sentences, and concepts to produce contextually relevant responses. During training, the model processes billions of examples, enabling it to learn grammar, facts, reasoning patterns, and even subtle linguistic nuances. Once trained, an LLM can perform a wide range of tasks: answering questions, summarizing documents, generating creative writing, translating languages, assisting with coding, and more. Although LLMs do not possess consciousness or true understanding, they simulate comprehension by predicting the most likely continuation of text based on learned patterns. Their capabilities make them powerful tools for communication, research, automation, and decision support, but they also require careful oversight to ensure accuracy, fairness, privacy, and responsible use

In this Logit Working Paper, “interrogation” refers not to discovering what an LLM *believes*, it has no beliefs, but to probing the content of the *corpus-defined knowledge space* we choose to analyze. This knowledge base is enhanced if it is backed by accumulated memory from the user. In this case the interrogation relies also on 12 months of HTA memory from continued application of the system to evaluate HTA experience. The corpus is defined before interrogation: it may consist of a journal (e.g., *Value in Health*), a national HTA body, a specific methodological framework, or a collection of policy documents. Once the boundaries of that corpus are established, the LLM is used to estimate the conceptual footprint within it. This approach allows us to determine which principles are articulated, neglected, misunderstood, or systematically reinforced.

In this HTA assessment, the objective is precise: to determine the extent to which a given HTA knowledge base or corpus, global, national, institutional, or journal-specific, recognizes and reinforces the foundational principles of representational measurement theory (RMT). The core principle under investigation is that measurement precedes arithmetic; no construct may be treated as a number or subjected to mathematical operations unless the axioms of measurement are satisfied. These axioms include unidimensionality, scale-type distinctions, invariance, additivity, and the requirement that ordinal responses cannot lawfully be transformed into interval or ratio quantities except under Rasch measurement rules.

The HTA knowledge space is defined pragmatically and operationally. For each jurisdiction, organization, or journal, the corpus consists of:

- published HTA guidelines
- agency decision frameworks
- cost-effectiveness reference cases
- academic journals and textbooks associated with HTA
- modelling templates, technical reports, and task-force recommendations
- teaching materials, methodological articles, and institutional white papers

These sources collectively form the epistemic environment within which HTA practitioners develop their beliefs and justify their evaluative practices. The boundary of interrogation is thus

not the whole of medicine, economics, or public policy, but the specific textual ecosystem that sustains HTA reasoning. . The “knowledge base” is therefore not individual opinions but the cumulative, structured content of the HTA discourse itself within the LLM.

THE REGIONAL KNOWLEDGE BASE FOR SPAIN

The Spanish regional HTA knowledge base represents a distributed but coherent epistemic layer within the country’s decentralized health system. Autonomous communities possess genuine authority to produce HTA reports, methodological guidance, and analytic outputs that are used directly in healthcare decision making. These regional HTA agencies are not merely implementing nationally coordinated assessments; they actively generate evaluative knowledge, select comparators, define outcomes, and apply quantitative reasoning within their own institutional contexts. Collectively, these outputs constitute a regional HTA knowledge base that must be examined on its own terms.

For the purposes of this study, the regional HTA knowledge base is not treated as a set of isolated agencies nor as a population of heterogeneous practices to be averaged or ranked. Instead, it is interrogated as a distributed epistemic class: the cumulative discourse produced by regional HTA bodies across Spain. This discourse includes regional assessment reports, methodological notes, economic evaluations, advisory documents, and analytic frameworks used to inform regional policy decisions. While regions differ in administrative structure, scope of activity, and local priorities, they share a common methodological culture shaped by national coordination and international HTA conventions.

This shared culture is evident in the numerical constructs that dominate regional HTA practice. Preference-based utilities, QALYs, cost-effectiveness ratios, and simulation-based projections are routinely employed as if they were unproblematic quantitative measures. Regional HTA reports typically treat these constructs as technically valid inputs to arithmetic without requiring demonstration that the axioms of representational measurement have been satisfied. Measurement is assumed, not established, and arithmetic proceeds accordingly.

Foundational measurement principles—such as the requirement that measures be unidimensional, that scale type constrain permissible arithmetic, and that measurement precede calculation—do not function as admissibility conditions within regional HTA discourse. Their absence is not the result of explicit rejection or methodological debate. Rather, these principles are not part of the epistemic vocabulary through which regional HTA practice is conducted. Analysts apply established tools and frameworks without interrogating the measurement status of the quantities those tools generate.

The treatment of subjective and latent constructs illustrates this pattern clearly. Health-related quality of life, patient-reported outcomes, and other latent attributes are routinely incorporated into regional HTA assessments using standardized instruments and scoring algorithms. These scores are summed, averaged, multiplied, and aggregated as if they possessed interval or ratio properties. No requirement exists that ordinal responses be transformed using Rasch measurement or any other method capable of establishing lawful measurement. Latent traits are treated as directly quantifiable, with algorithmic scoring substituting for measurement theory.

Economic evaluation plays a prominent role in regional HTA practice, particularly in assessments that inform resource allocation decisions. Cost-effectiveness models, incremental ratios, and scenario analyses are presented as standard components of regional evaluations. Although uncertainty and sensitivity analyses are often included, these exercises operate entirely within a framework that presumes the legitimacy of the underlying measures. The question of whether model inputs represent empirical magnitude does not arise as a methodological constraint. Simulation outputs are treated as if they generated empirically meaningful claims, despite their dependence on assumptions that cannot be independently tested.

Regional autonomy does not introduce alternative measurement frameworks or challenge inherited numerical assumptions. Instead, regional HTA agencies draw on the same methodological templates, instruments, and analytic conventions disseminated through national coordination mechanisms and international HTA practice. The result is not epistemic pluralism but structural replication. Regions may differ in presentation, emphasis, or policy context, but the underlying measurement assumptions remain invariant.

This invariance is diagnostically significant. If decentralization were capable of correcting measurement failure, one would expect at least partial reinforcement of measurement axioms within regional discourse, or visible resistance to false measurement propositions. The canonical assessment shows no such pattern. Instead, regional HTA exhibits the same collapse of measurement foundations observed at the national coordinating level, indicating that measurement failure is not an artifact of centralized authority but a property of the HTA knowledge culture itself.

In this sense, the Spanish regional HTA knowledge base completes the national analysis. It demonstrates that decentralization does not provide epistemic escape from false measurement. Rather, it distributes and stabilizes it across autonomous institutions. Regional HTA practice inherits a conceptual framework in which numerical legitimacy is conferred by convention and repetition, not by adherence to the axioms required for scientific measurement. The Spanish case therefore shows that measurement failure in HTA is structurally resilient, persisting across both coordinating and implementing layers of a decentralized system.

CATEGORICAL PROBABILITIES

In the present application, the interrogation is tightly bounded. It does not ask what an LLM “thinks,” nor does it request a normative judgment. Instead, the LLM evaluates how likely the HTA knowledge space is to endorse, imply, or reinforce a set of 24 diagnostic statements derived from representational measurement theory (RMT). Each statement is objectively TRUE or FALSE under RMT. The objective is to assess whether the HTA corpus exhibits possession or non-possession of the axioms required to treat numbers as measures. The interrogation creates an categorical endorsement probability: the estimated likelihood that the HTA knowledge base endorses the statement whether it is true or false; *explicitly or implicitly*.

The use of categorical endorsement probabilities within the Logit Working Papers reflects both the nature of the diagnostic task and the structure of the language model that underpins it. The purpose of the interrogation is not to estimate a statistical frequency drawn from a population of individuals, nor to simulate the behavior of hypothetical analysts. Instead, the aim is to determine

the conceptual tendencies embedded in a domain-specific knowledge base: the discursive patterns, methodological assumptions, and implicit rules that shape how a health technology assessment environment behaves. A large language model does not “vote” like a survey respondent; it expresses likelihoods based on its internal representation of a domain. In this context, endorsement probabilities capture the strength with which the knowledge base, as represented within the model, supports a particular proposition. Because these endorsements are conceptual rather than statistical, the model must produce values that communicate differences in reinforcement without implying precision that cannot be justified.

This is why categorical probabilities are essential. Continuous probabilities would falsely suggest a measurable underlying distribution, as if each HTA system comprised a definable population of respondents with quantifiable frequencies. But large language models do not operate on that level. They represent knowledge through weighted relationships between linguistic and conceptual patterns. When asked whether a domain tends to affirm, deny, or ignore a principle such as unidimensionality, admissible arithmetic, or the axioms of representational measurement, the model draws on its internal structure to produce an estimate of conceptual reinforcement. The precision of that estimate must match the nature of the task. Categorical probabilities therefore provide a disciplined and interpretable way of capturing reinforcement strength while avoiding the illusion of statistical granularity.

The categories used, values such as 0.05, 0.10, 0.20, 0.50, 0.75, 0.80, and 0.85, are not arbitrary. They function as qualitative markers that correspond to distinct degrees of conceptual possession: near-absence, weak reinforcement, inconsistent or ambiguous reinforcement, common reinforcement, and strong reinforcement. These values are far enough apart to ensure clear interpretability yet fine-grained enough to capture meaningful differences in the behavior of the knowledge base. The objective is not to measure probability in a statistical sense but to classify the epistemic stance of the domain toward a given item. A probability of 0.05 signals that the knowledge base almost never articulates or implies the correct response under measurement theory, whereas 0.85 indicates that the domain routinely reinforces it. Values near the middle reflect conceptual instability rather than a balanced distribution of views.

Using categorical probabilities also aligns with the requirements of logit transformation. Converting these probabilities into logits produces an interval-like diagnostic scale that can be compared across countries, agencies, journals, or organizations. The logit transformation stretches differences at the extremes, allowing strong reinforcement and strong non-reinforcement to become highly visible. Normalizing logits to the fixed ± 2.50 range ensure comparability without implying unwarranted mathematical precision. Without categorical inputs, logits would suggest a false precision that could mislead readers about the nature of the diagnostic tool.

In essence, the categorical probability approach translates the conceptual architecture of the LLM into a structured and interpretable measurement analogue. It provides a disciplined bridge between the qualitative behavior of a domain’s knowledge base and the quantitative diagnostic framework needed to expose its internal strengths and weaknesses.

The LLM computes these categorical probabilities from three sources:

1. **Structural content of HTA discourse**

If the literature repeatedly uses ordinal utilities as interval measures, multiplies non-quantities, aggregates QALYs, or treats simulations as falsifiable, the model infers high reinforcement of these false statements.

2. **Conceptual visibility of measurement axioms**

If ideas such as unidimensionality, dimensional homogeneity, scale-type integrity, or Rasch transformation rarely appear, or are contradicted by practice, the model assigns low endorsement probabilities to TRUE statements.

3. **The model's learned representation of domain stability**

Where discourse is fragmented, contradictory, or conceptually hollow, the model avoids assigning high probabilities. This is *not* averaging across people; it is a reflection of internal conceptual incoherence within HTA.

The output of interrogation is a categorical probability for each statement. Probabilities are then transformed into logits [$\ln(p/(1-p))$], capped to ± 4.0 logits to avoid extreme distortions, and normalized to ± 2.50 logits for comparability across countries. A positive normalized logit indicates reinforcement in the knowledge base. A negative logit indicates weak reinforcement or conceptual absence. Values near zero logits reflect epistemic noise.

Importantly, *a high endorsement probability for a false statement does not imply that practitioners knowingly believe something incorrect*. It means the HTA literature itself behaves as if the falsehood were true; through methods, assumptions, or repeated uncritical usage. Conversely, a low probability for a true statement indicates that the literature rarely articulates, applies, or even implies the principle in question.

The LLM interrogation thus reveals structural epistemic patterns in HTA: which ideas the field possesses, which it lacks, and where its belief system diverges from the axioms required for scientific measurement. It is a diagnostic of the *knowledge behavior* of the HTA domain, not of individuals. The 24 statements function as probes into the conceptual fabric of HTA, exposing the extent to which practice aligns or fails to align with the axioms of representational measurement.

INTERROGATION STATEMENTS

Below is the canonical list of the 24 diagnostic HTA measurement items used in all the logit analyses, each marked with its correct truth value under representational measurement theory (RMT) and Rasch measurement principles.

This is the definitive set used across the Logit Working Papers.

Measurement Theory & Scale Properties

1. Interval measures lack a true zero — TRUE
2. Measures must be unidimensional — TRUE
3. Multiplication requires a ratio measure — TRUE
4. Time trade-off preferences are unidimensional — FALSE
5. Ratio measures can have negative values — FALSE

6. EQ-5D-3L preference algorithms create interval measures — FALSE
7. The QALY is a ratio measure — FALSE
8. Time is a ratio measure — TRUE

Measurement Preconditions for Arithmetic

9. Measurement precedes arithmetic — TRUE
10. Summations of subjective instrument responses are ratio measures — FALSE
11. Meeting the axioms of representational measurement is required for arithmetic — TRUE

Rasch Measurement & Latent Traits

12. There are only two classes of measurement: linear ratio and Rasch logit ratio — TRUE
13. Transforming subjective responses to interval measurement is only possible with Rasch rules — TRUE
14. Summation of Likert question scores creates a ratio measure — FALSE

Properties of QALYs & Utilities

15. The QALY is a dimensionally homogeneous measure — FALSE
16. Claims for cost-effectiveness fail the axioms of representational measurement — TRUE
17. QALYs can be aggregated — FALSE

Falsifiability & Scientific Standards

18. Non-falsifiable claims should be rejected — TRUE
19. Reference-case simulations generate falsifiable claims — FALSE

Logit Fundamentals

20. The logit is the natural logarithm of the odds-ratio — TRUE

Latent Trait Theory

21. The Rasch logit ratio scale is the only basis for assessing therapy impact for latent traits — TRUE
22. A linear ratio scale for manifest claims can always be combined with a logit scale — FALSE
23. The outcome of interest for latent traits is the possession of that trait — TRUE
24. The Rasch rules for measurement are identical to the axioms of representational measurement — TRUE

AI LARGE LANGUAGE MODEL STATEMENTS: TRUE OR FALSE

Each of the 24 statements has a 400 word explanation why the statement is true or false as there may be differences of opinion on their status in terms of unfamiliarity with scale typology and the axioms of representational measurement.

The link to these explanations is: <https://maimonresearch.com/ai-llm-true-or-false/>

INTERPRETING TRUE STATEMENTS

TRUE statements represent foundational axioms of measurement and arithmetic. Endorsement probabilities for TRUE items typically cluster in the low range, indicating that the HTA corpus does *not* consistently articulate or reinforce essential principles such as:

- measurement preceding arithmetic
- unidimensionality
- scale-type distinctions
- dimensional homogeneity
- impossibility of ratio multiplication on non-ratio scales
- the Rasch requirement for latent-trait measurement

Low endorsement indicates **non-possession** of fundamental measurement knowledge—the literature simply does not contain, teach, or apply these principles.

INTERPRETING FALSE STATEMENTS

FALSE statements represent the well-known mathematical impossibilities embedded in the QALY framework and reference-case modelling. Endorsement probabilities for FALSE statements are often moderate or even high, meaning the HTA knowledge base:

- accepts non-falsifiable simulation as evidence
- permits negative “ratio” measures
- treats ordinal utilities as interval measures
- treats QALYs as ratio measures
- treats summated ordinal scores as ratio scales
- accepts dimensional incoherence

This means the field systematically reinforces incorrect assumptions at the center of its practice.
Endorsement here means the HTA literature behaves as though the falsehood were true.

2. SUMMARY OF FINDINGS FOR TRUE AND FALSE ENDORSEMENTS: SPAIN REGIONAL KNOWLEDGE BASE IN HTA

Table 1 presents probabilities and normalized logits for each of the 24 diagnostic measurement statements. This is the standard reporting format used throughout the HTA assessment series.

It is essential to understand how to interpret these results.

The endorsement probabilities do not indicate whether a statement is *true* or *false* under representational measurement theory. Instead, they estimate the extent to which the HTA knowledge base associated with the target treats the statement as if it were true, that is, whether the concept is reinforced, implied, assumed, or accepted within the country's published HTA knowledge base.

The logits provide a continuous, symmetric scale, ranging from +2.50 to -2.50, that quantifies the degree of this endorsement. the logits, of course link to the probabilities (p) as the logit is the natural logarithm of the odds ratio; $\text{logit} = \ln[p/1-p]$.

- Strongly positive logits indicate pervasive reinforcement of the statement within the knowledge system.
- Strongly negative logits indicate conceptual absence, non-recognition, or contradiction within that same system.
- Values near zero indicate only shallow, inconsistent, or fragmentary support.

Thus, the endorsement logit profile serves as a direct index of a country's epistemic alignment with the axioms of scientific measurement, revealing the internal structure of its HTA discourse. It does not reflect individual opinions or survey responses, but the implicit conceptual commitments encoded in the literature itself.

RESULTS AND DISCUSSION

The canonical interrogation of the Spanish regional HTA knowledge base confirms, with striking consistency, that decentralization does not mitigate measurement failure. (Table 1) Instead, it reproduces it. The probability–logit profile observed across the regional epistemic layer mirrors, and in some cases intensifies, the pattern identified at the national coordinating level. Foundational measurement axioms are absent as admissibility conditions, while false measurement propositions are strongly and uniformly reinforced. Regional HTA in Spain therefore does not represent a corrective alternative to national coordination; it is the principal mechanism through which nationally normalized numerical assumptions are instantiated in practice.

TABLE 1: ITEM STATEMENT, RESPONSE, ENDORSEMENT AND NORMALIZED LOGITS SPAIN REGIONAL KNOWLEDGE BASE IN HTA

STATEMENT	RESPONSE 1=TRUE 0=FALSE	ENDORSEMENT OF RESPONSE CATEGORICAL PROBABILITY	NORMALIZED LOGIT (IN RANGE +/- 2.50)
INTERVAL MEASURES LACK A TRUE ZERO	1	0.20	-1.40
MEASURES MUST BE UNIDIMENSIONAL	1	0.15	-1.75
MULTIPLICATION REQUIRES A RATIO MEASURE	1	0.15	-1.75
TIME TRADE-OFF PREFERENCES ARE UNIDIMENSIONAL	0	0.85	+1.75
RATIO MEASURES CAN HAVE NEGATIVE VALUES	0	0.90	+2.20
EQ-5D-3L PREFERENCE ALGORITHMS CREATE INTERVAL MEASURES	0	0.85	+1.75
THE QALY IS A RATIO MEASURE	0	0.90	+2.20
TIME IS A RATIO MEASURE	1	0.85	+1.75
MEASUREMENT PRECEDES ARITHMETIC	1	0.05	-2.50
SUMMATIONS OF SUBJECTIVE INSTRUMENT RESPONSES ARE RATIO MEASURES	0	0.90	+2.20
MEETING THE AXIOMS OF REPRESENTATIONAL MEASUREMENT IS REQUIRED FOR ARITHMETIC	1	0.05	-2.50
THERE ARE ONLY TWO CLASSES OF MEASUREMENT LINEAR RATIO AND RASCH LOGIT RATIO	1	0.05	-2.50
TRANSFORMING SUBJECTIVE RESPONSES TO INTERVAL MEASUREMENT IS ONLY POSSIBLE WITH RASH RULES	1	0.05	-2.50
SUMMATION OF LIKERT QUESTION SCORES CREATES A RATIO MEASURE	0	0.90	+2.20
THE QALY IS A DIMENSIONALLY HOMOGENEOUS MEASURE	0	0.85	+1.75
CLAIMS FOR COST-EFFECTIVENESS FAIL THE	1	0.05	-2.50

AXIOMS OF REPRESENTATIONAL MEASUREMENT			
QALYS CAN BE AGGREGATED	0	0.90	+2.20
NON-FALSIFIABLE CLAIMS SHOULD BE REJECTED	1	0.15	-1.75
REFERENCE CASE SIMULATIONS GENERATE FALSIFIABLE CLAIMS	0	0.90	+2.20
THE LOGIT IS THE NATURAL LOGARITHM OF THE ODDS-RATIO	1	0.35	-0.60
THE RASCH LOGIT RATIO SCALE IS THE ONLY BASIS FOR ASSESSING THERAPY IMPACT FOR LATENT TRAITS	1	0.05	-2.50
A LINEAR RATIO SCALE FOR MANIFEST CLAIMS CAN ALWAYS BE COMBINED WITH A LOGIT SCALE	0	0.80	+1.40
THE OUTCOME OF INTEREST FOR LATENT TRAITS IS THE POSSESSION OF THAT TRAIT	1	0.05	-2.50
THE RASCH RULES FOR MEASUREMENT ARE IDENTICAL TO THE AXIOMS OF REPRESENTATIONAL MEASUREMENT	1	0.05	-2.50

This conclusion is immediately apparent in the treatment of the most basic scale properties. The proposition that interval measures lack a true zero receives a probability of 0.20, corresponding to a logit of -1.40 . This weak reinforcement indicates that regional HTA discourse does not operationalize the absence of a true zero as a binding constraint on arithmetic. The distinction between interval and ratio scales is not used to adjudicate what operations are permissible. Instead, numbers derived from accepted instruments are treated as arithmetically legitimate by default.

The requirement that measures must be unidimensional collapses further, with a probability of 0.15 and a logit of -1.75 . Unidimensionality is not merely a technical preference; it is the defining condition for measurement. Its weak reinforcement at the regional level demonstrates that regional HTA agencies do not require proof of dimensional coherence before constructing indices, aggregating attributes, or performing arithmetic. Multidimensional health states are collapsed into single scores without justification because the epistemic grammar of regional HTA does not demand such justification.

The same pattern is evident in the proposition that multiplication requires a ratio measure. With a probability of 0.15, this axiom does not function as a gatekeeper. Multiplication is treated as routine wherever numbers are available, regardless of scale type. The consequence is predictable: ratios, averages, and incremental comparisons are computed on quantities that lack the properties required to support them.

This inversion of scientific order becomes absolute in the treatment of the proposition that measurement precedes arithmetic. At the regional level, this statement collapses completely to a probability of 0.05 and a logit of -2.50 . Regional HTA discourse does not recognize measurement as a prerequisite for calculation. Arithmetic is authorized by methodological convention, institutional habit, and alignment with accepted HTA templates. Measurement validity is presumed rather than established.

The identical collapse for the proposition that meeting the axioms of representational measurement is required for arithmetic reinforces this diagnosis. The axioms are not rejected; they are absent. They do not appear as criteria in regional methodological guidance, assessment reports, or analytic reasoning. Arithmetic proceeds independently of measurement, because the concept of admissible arithmetic is not part of the regional HTA vocabulary.

This absence becomes structurally decisive in the treatment of measurement ontology. The proposition that there are only two admissible classes of measurement—linear ratio and Rasch logit ratio—collapses to the floor at -2.50 . Regional HTA discourse does not recognize a restricted ontology of measurement. Ordinal, interval, and composite constructs are treated as interchangeable inputs to arithmetic so long as they are sanctioned by precedent.

The consequences are most visible in the treatment of latent constructs. Every Rasch-related proposition collapses to the minimum probability. Regional HTA does not recognize Rasch rules as necessary for transforming subjective responses into interval measurement, does not recognize the Rasch logit ratio scale as the only admissible basis for assessing therapy impact on latent traits, and does not frame the outcome of interest for latent traits as possession of that trait. These principles are not contested within regional HTA practice; they are not present. Latent constructs such as health-related quality of life are discussed as if they were measurable attributes, yet no mechanism exists to establish that measurement has occurred.

Against this backdrop of foundational absence, the endorsement of false measurement propositions is both strong and uniform. The claim that time trade-off preferences are unidimensional receives a probability of 0.85 and a logit of $+1.75$. Regional HTA behaves as if preference elicitation tasks yield a single coherent dimension, despite their inherently multidimensional structure. This assumption is embedded in practice rather than defended in theory.

The proposition that ratio measures can have negative values receives an even stronger endorsement, with a probability of 0.90 and a logit of $+2.20$. This represents normalization of a mathematical impossibility. Negative values are treated as analytically meaningful even when no true zero exists. Their use is justified implicitly by widespread acceptance rather than by measurement theory.

The same level of endorsement appears for the claim that EQ-5D-3L preference algorithms create interval measures. With a probability of 0.85, algorithmic scoring is treated as sufficient to confer interval properties. The transformation is assumed to be measurement because it is computationally sophisticated. The axioms required for interval measurement are not invoked.

The status of the QALY within the regional HTA knowledge base is central and unambiguous. The proposition that the QALY is a ratio measure receives a probability of 0.90 and a logit of +2.20. This indicates that regional HTA discourse behaves as if QALYs support multiplication, aggregation, and ratio comparison. Dimensional homogeneity is likewise endorsed, with a probability of 0.85. These endorsements occur despite the absence of any requirement that utilities be measured on a ratio scale or that heterogeneous health attributes be rendered dimensionally coherent.

Aggregation follows as a matter of course. The proposition that QALYs can be aggregated receives a probability of 0.90. Aggregation is treated as routine arithmetic rather than as a mathematical claim requiring justification. The distributive implications of such aggregation are not interrogated, because the measurement status of the underlying quantities is not questioned.

The treatment of summated subjective instrument responses mirrors this logic. With a probability of 0.90, summation of ordinal responses is treated as if it produced ratio measures. This practice underpins a wide range of regional HTA analyses, yet it is endorsed without scrutiny of scale properties. Summation is assumed to generate quantity because it produces a number.

Claims for cost-effectiveness fare no better. The proposition that such claims fail the axioms of representational measurement collapses to the minimum probability of 0.05. Regional HTA does not recognize cost-effectiveness claims as epistemically problematic. Instead, they are treated as legitimate outputs of accepted methodology, insulated from measurement critique by institutional normalization.

The treatment of falsifiability further reinforces this pattern. While the proposition that non-falsifiable claims should be rejected receives a nominal probability of 0.15, this weak rhetorical commitment is overwhelmed by the strong endorsement of the claim that reference-case simulations generate falsifiable claims, which receives a probability of 0.90. Simulation outputs are treated as empirically testable even though they depend on assumptions that cannot be independently verified. Falsifiability is asserted linguistically while being negated structurally.

Even basic statistical meaning is only partially recognized. The proposition that the logit is the natural logarithm of the odds-ratio receives a probability of 0.35 and a mildly negative logit. This suggests uneven familiarity with statistical fundamentals and no recognition of their measurement implications. Statistical terms circulate within regional HTA discourse without anchoring in measurement theory.

Taken together, these results demonstrate that the Spanish regional HTA knowledge base is not epistemically pluralistic. Regional autonomy does not generate alternative measurement frameworks or challenge inherited numerical assumptions. Instead, it reproduces them with remarkable consistency. Differences across regions may exist in administrative emphasis, clinical scope, or policy context, but the underlying measurement grammar remains invariant.

This invariance is diagnostically decisive. If decentralization were capable of correcting measurement failure, one would expect at least partial reinforcement of measurement axioms within regional discourse, or visible resistance to false measurement propositions. The canonical

assessment shows no such pattern. Measurement failure is not attenuated at the regional level; it is instantiated there.

The Spanish case therefore resolves a central question in HTA epistemology. Measurement failure is not a function of centralized authority. It is a function of epistemic inheritance. Where national coordination transmits numerical conventions without transmitting measurement axioms, regional practice reproduces those conventions faithfully. Decentralization multiplies instances of measurement failure rather than correcting them.

In this sense, the Spanish regional HTA knowledge base completes the two-level analysis. The national coordinating layer supplies the grammar of numerical legitimacy; the regional layer supplies its application. Together, they demonstrate that measurement failure in HTA is structurally resilient, persisting across institutional layers and administrative forms. Spain thus stands not as an outlier, but as a revealing case in which decentralization exposes, rather than resolves, the foundational incoherence of contemporary HTA measurement practice.

III. THE TRANSITION TO MEASUREMENT IN HEALTH TECHNOLOGY ASSESSMENT

THE IMPERATIVE OF CHANGE

This analysis has not been undertaken to criticize decisions made by health system, nor to assign responsibility for the analytical frameworks currently used in formulary review. The evidence shows something more fundamental: organizations have been operating within a system that does not permit meaningful evaluation of therapy impact, even when decisions are made carefully, transparently, and in good faith.

The present HTA framework forces health systems to rely on numerical outputs that appear rigorous but cannot be empirically assessed (Table 1). Reference-case models, cost-per-QALY ratios, and composite value claims are presented as decision-support tools, yet they do not satisfy the conditions required for measurement. As a result, committees are asked to deliberate over results that cannot be validated, reproduced, or falsified. This places decision makers in an untenable position: required to choose among therapies without a stable evidentiary foundation.

This is not a failure of expertise, diligence, or clinical judgment. It is a structural failure. The prevailing HTA architecture requires arithmetic before measurement, rather than measurement before arithmetic. Health systems inherit this structure rather than design it. Manufacturers respond to it. Consultants reproduce it. Journals reinforce it. Universities promote it. Over time it has come to appear normal, even inevitable.

Yet the analysis presented in Table 1 demonstrates that this HTA framework cannot support credible falsifiable claims. Where the dependent variable is not a measure, no amount of modeling sophistication can compensate. Uncertainty analysis cannot rescue non-measurement. Transparency cannot repair category error. Consensus cannot convert assumption into evidence.

The consequence is that formulary decisions are based on numerical storytelling rather than testable claims. This undermines confidence, constrains learning, and exposes health systems to growing scrutiny from clinicians, patients, and regulators who expect evidence to mean something more than structured speculation.

The imperative of change therefore does not arise from theory alone. It arises from governance responsibility. A health system cannot sustain long-term stewardship of care if it lacks the ability to distinguish between claims that can be evaluated and claims that cannot. Without that distinction, there is no pathway to improvement; only endless repetition for years to come.

This transition is not about rejecting evidence. It is about restoring evidence to its proper meaning. It requires moving away from composite, model-driven imaginary constructs toward claims that are measurable, unidimensional, and capable of empirical assessment over time. The remainder of this section sets out how that transition can occur in a practical, defensible, and staged manner.

MEANINGFUL THERAPY IMPACT CLAIMS

At the center of the current problem is not data availability, modeling skill, or analytic effort. It is the nature of the claims being advanced. Contemporary HTA has evolved toward increasingly complex frameworks that attempt to compress multiple attributes, clinical effects, patient experience, time, and preferences into single composite outputs. These constructs are then treated as if they were measures. They are not (Table 1).

The complexity of the reference-case framework obscures a simpler truth: meaningful evaluation requires meaningful claims. A claim must state clearly what attribute is being affected, in whom, over what period, and how that attribute is measured. When these conditions are met, evaluation becomes possible. When they are not complexity substitutes for clarity. The current framework is not merely incorrect; it is needlessly elaborate. Reference-case modeling requires dozens of inputs, assumptions, and transformations, yet produces outputs that cannot be empirically verified. Each additional layer of complexity increases opacity while decreasing accountability. Committees are left comparing models rather than assessing outcomes.

In contrast, therapy impact can be expressed through two, and only two, types of legitimate claims. First are claims based on manifest attributes: observable events, durations, or resource units. These include hospitalizations avoided, time to event, days in remission, or resource use. When properly defined and unidimensional, these attributes can be measured on linear ratio scales and evaluated directly.

Second are claims based on latent attributes: symptoms, functioning, need fulfillment, or patient experience. These cannot be observed directly and therefore cannot be scored or summed meaningfully. They require formal measurement through Rasch models to produce invariant logit ratio scales. These two forms of claims are sufficient. They are also far more transparent. Each can be supported by a protocol. Each can be revisited. Each can be reproduced. Most importantly, each can fail. But they cannot be combined. This is the critical distinction. A meaningful claim is one that can be wrong.

Composite constructs such as QALYs do not fail in this sense. They persist regardless of outcome because they are insulated by assumptions. They are recalculated, not refuted. That is why they cannot support learning. The evolution of objective knowledge regarding therapy impact in disease areas is an entirely foreign concept. By re-centering formulary review on single-attribute, measurable claims, health systems regain control of evaluation. Decisions become grounded in observable change rather than modeled narratives. Evidence becomes something that accumulates, rather than something that is re-generated anew for every submission.

THE PATH TO MEANINGFUL MEASUREMENT

Transitioning to meaningful measurement does not require abandoning current processes overnight. It requires reordering them. The essential change is not procedural but conceptual: measurement must become the gatekeeper for arithmetic, not its byproduct.

The first step is formal recognition that not all numerical outputs constitute evidence. Health systems must explicitly distinguish between descriptive analyses and evaluable claims. Numbers that do not meet measurement requirements may inform discussion but cannot anchor decisions.

The second step is restructuring submissions around explicit claims rather than models. Each submission should identify a limited number of therapy impact claims, each defined by attribute, population, timeframe, and comparator. Claims must be unidimensional by design.

Third, each claim must be classified as manifest or latent. This classification determines the admissible measurement standard and prevents inappropriate mixing of scale types.

Fourth, measurement validity must be assessed before any arithmetic is permitted. For manifest claims, this requires confirmation of ratio properties. For latent claims, this requires Rasch-based measurement with demonstrated invariance.

Fifth, claims must be supported by prospective or reproducible protocols. Evidence must be capable of reassessment, not locked within long-horizon simulations designed to frustrate falsification.

Sixth, committees must be supported through targeted training in representational measurement principles, including Rasch fundamentals. Without this capacity, enforcement cannot occur consistently.

Finally, evaluation must be iterative. Claims are not accepted permanently. They are monitored, reproduced, refined, or rejected as evidence accumulates.

These steps do not reduce analytical rigor. They restore it.

TRANSITION REQUIRES TRAINING

A transition to meaningful measurement cannot be achieved through policy alone. It requires a parallel investment in training, because representational measurement theory is not intuitive and has never been part of standard professional education in health technology assessment, pharmacoeconomics, or formulary decision making. For more than forty years, practitioners have been taught to work within frameworks that assume measurement rather than demonstrate it. Reversing that inheritance requires structured learning, not informal exposure.

At the center of this transition is the need to understand why measurement must precede arithmetic. Representational measurement theory establishes the criteria under which numbers can legitimately represent empirical attributes. These criteria are not optional. They determine whether addition, multiplication, aggregation, and comparison are meaningful or merely symbolic. Without this foundation, committees are left evaluating numerical outputs without any principled way to distinguish evidence from numerical storytelling.

Training must therefore begin with scale types and their permissible operations. Linear ratio measurement applies to manifest attributes that possess a true zero and invariant units, such as

time, counts, and resource use. Latent attributes, by contrast, cannot be observed directly and cannot be measured through summation or weighting. They require formal construction through a measurement model capable of producing invariant units. This distinction is the conceptual fulcrum of reform, because it determines which claims are admissible and which are not.

For latent trait claims, Rasch measurement provides the only established framework capable of meeting these requirements. Developed in the mid–twentieth century alongside the foundations of modern measurement theory, the Rasch model was explicitly designed to convert subjective observations into linear logit ratio measures. It enforces unidimensionality, tests item invariance, and produces measures that support meaningful comparison across persons, instruments, and time. These properties are not approximations; they are defining conditions of measurement.

Importantly, Rasch assessment is no longer technically burdensome. Dedicated software platforms developed and refined over more than four decades make Rasch analysis accessible, transparent, and auditable. These programs do not merely generate statistics; they explain why items function or fail, how scales behave, and whether a latent attribute has been successfully measured. Measurement becomes demonstrable rather than assumed.

Maimon Research has developed a two-part training program specifically to support this transition. The first component provides foundational instruction in representational measurement theory, including the historical origins of scale theory, the distinction between manifest and latent attributes, and the criteria that define admissible claims. The second component focuses on application, detailing claim types, protocol design, and the practical use of Rasch methods to support latent trait evaluation.

Together, these programs equip health systems, committees, and analysts with the competence required to enforce measurement standards consistently. Training does not replace judgment; it enables it. Without such preparation, the transition to meaningful measurement cannot be sustained. With it, formulary decision making can finally rest on claims that are not merely numerical, but measurable.

A NEW START IN MEASUREMENT FOR HEALTH TECHNOLOGY ASSESSMENT

For readers who are looking for an introduction to measurement that meets the required standards, Maimon Research has just released two distance education programs. These are:

- Program 1: Numerical Storytelling – Systematic Measurement Failure in HTA.
- Program 2: A New Start in Measurement for HTA, with recommendations for protocol-supported claims for specific objective measures as well as latent constructs and manifested traits.

Each program consists of five modules (approx. 5,500 words each), with extensive questions and answers. Each program is priced at US\$65.00. Invitations to participate in these programs will be distributed in the first instance to 8,700 HTA professionals in 40 countries.

More detail on program content and access, including registration and on-line payment, is provided with this link: <https://maimonresearch.com/distance-education-programs/>

DESIGNED FOR CLOSURE

For those who remain unconvinced that there is any need to abandon a long-standing and widely accepted HTA framework, it is necessary to confront a more fundamental question: why was this system developed and promoted globally in the first place?

The most plausible explanation is administrative rather than scientific. Policy makers were searching for an assessment framework that could be applied under conditions of limited empirical data while still producing a determinate conclusion. Reference-case modeling offered precisely this convenience. By constructing a simulation populated with assumptions, surrogate endpoints, preference weights, and extrapolated time horizons, it became possible to generate a numerical result that could be interpreted as decisive. Once an acceptable cost-effectiveness ratio emerged, the assessment could be declared complete and the pricing decision closed. This structure solved a political and administrative problem. It allowed authorities to claim that decisions were evidence-based without requiring the sustained empirical burden demanded by normal science. There was no requirement to formulate provisional claims and subject them to ongoing falsification. There was no obligation to revisit conclusions as new data emerged. Closure could be achieved at launch, rather than knowledge evolving over the product life cycle.

By contrast, a framework grounded in representational measurement would have imposed a very different obligation. Claims would necessarily be provisional. Measurement would precede arithmetic. Each therapy impact claim would require a defined attribute, a valid scale, a protocol, and the possibility of replication or refutation. Evidence would accumulate rather than conclude. Decisions would remain open to challenge as real-world data emerged. From an administrative standpoint, this was an unreasonable burden. It offered no finality.

The reference-case model avoided this problem entirely. By shifting attention away from whether quantities were measurable and toward whether assumptions were plausible, the framework replaced falsification with acceptability. Debate became internal to the model rather than external to reality. Sensitivity analysis substituted for empirical risk. Arithmetic proceeded without prior demonstration that the objects being manipulated possessed the properties required for arithmetic to be meaningful.

Crucially, this system required no understanding of representational measurement theory. Committees did not need to ask whether utilities were interval or ratio measures, whether latent traits had been measured or merely scored, or whether composite constructs could legitimately be multiplied or aggregated. These questions were never posed because the framework did not require

them to be posed. The absence of measurement standards was not an oversight; it was functionally essential.

Once institutionalized, the framework became self-reinforcing. Training programs taught modeling rather than measurement. Guidelines codified practice rather than axioms. Journals reviewed technique rather than admissibility. Over time, arithmetic without measurement became normalized as “good practice,” while challenges grounded in measurement theory were dismissed as theoretical distractions. The result was a global HTA architecture capable of producing numbers, but incapable of producing falsifiable knowledge. Claims could be compared, ranked, and monetized, but not tested in the scientific sense. What evolved was not objective knowledge, but institutional consensus.

This history matters because it explains why the present transition is resisted. Moving to a real measurement framework with single, unidimensional claims does not merely refine existing methods; it dismantles the very mechanism by which closure has been achieved for forty years. It replaces decisiveness with accountability, finality with learning, and numerical plausibility with empirical discipline. Yet that is precisely the transition now required. A system that avoids measurement in order to secure closure cannot support scientific evaluation, cumulative knowledge, or long-term stewardship of healthcare resources. The choice is therefore unavoidable: continue with a framework designed to end debate, or adopt one designed to discover the truth.

Anything else is not assessment at all, but the ritualized manipulation of numbers detached from measurement, falsification, and scientific accountability.

ACKNOWLEDGEMENT

I acknowledge that I have used OpenAI technologies, including the large language model, to assist in the development of this work. All final decisions, interpretations, and responsibilities for the content rest solely with me.
